Disentangling the Effects of Financial Inclusion on Household Well-Being

March 18, 2023

Abstract

Recent studies show that financial inclusion has a positive impact on household financial well-being, but the specific mechanisms that underlie this relationship remain unclear. The "household demand" view proposes that financial inclusion leads to higher consumption by households through increased borrowing, while the "business finance" view suggests that financial inclusion benefits households indirectly through the labor market. Exploiting a regression discontinuity design based on a major bank-branch expansion policy in India, and panel data on households and census data on enterprises, we study the general equilibrium effects of financial inclusion. We find that treated households significantly increase consumption expenditures, savings, and investments, but without increasing loans or debt. In contrast, treated enterprises borrow more, employ more workers, earn higher profits, and pay higher wages. Lastly, we show evidence that banks find it more profitable to lend to firms rather than households. Overall, our findings suggest that financial inclusion has important spillover effects on the wider economy, with benefits accruing to households through the labor market.

1 Introduction

A large literature finds that financial inclusion enhances household consumption and reduces poverty [Burgess and Pande, 2005; Beck et al., 2007; Breza and Kinnan, 2021] However, our understanding of the underlying mechanisms that generate these outcomes remains limited. One view is that financial inclusion allows households to finance increased consumption via greater borrowing. Under this "household demand" channel, credit supply expansion has a real impact on the economy through households [Mian and Sufi, 2018; Mian et al., 2019].

An alternative view is that expanding access to finance allows financially constrained firms to borrow more and hire additional workers [Bruhn and Love, 2014; Chodorow-Reich, 2014; Bai et al., 2018; Dehejia and Gupta, 2022]. According to this "business finance" channel, households benefit from financial inclusion indirectly in the labor market through a rise in employment opportunities and earnings. From a policy standpoint, it is critical to discern which of these two mechanisms has a greater impact to ensure the effective targeting of financial inclusion policies. In this paper, we differentiate between these mechanisms by studying the causal impact of bank branch expansion on households and enterprises.

Using a regression discontinuity (RD) design based on a major bank branch expansion policy in India, and panel data on households and firms, we find evidence in support of the "business finance" mechanism. Financial inclusion increases household expenditures, savings, and investments, but without increasing household borrowing and debt. Instead, we observe a rise in the borrowing, employment, and wage bill of firms. Studying the lending incentives of banks, our results suggest that banks find it more profitable to lend to firms rather than households. We find that banks expand credit more in urban areas where there is a higher concentration of firms and the labor market benefits of financial inclusion accrue to richer, socially advantaged, urban households.

The main contributions of our study are as follows: First, we differentiate the "household demand" and "business finance" effects of financial inclusion. For example, Breza and Kinnan [2021] study the impact of micro-credit on rural households in an Indian state, but do not distinguish between these mechanisms, and Dehejia and Gupta [2022] show that improved access to finance moves households from informal self-employment to formal employment in firms, but do not study the impact on financial well-being. Second, we show that financial inclusion is likely to have a different impact on households in developing economies compared to developed countries.

For instance, Célerier and Matray [2019] show that bank branch deregulation in the U.S. increased both consumption expenditures and household debt. Third, we show that bank lending incentives can explain the results. To our knowledge, our paper is the first to study the general equilibrium effects of bank branch expansion on household financial well-being.

We investigate the causal mechanisms through which financial inclusion affects household financial well-being with a regression discontinuity (RD) design, leveraging panel data on households and census data on enterprises. Our RD design is built upon a significant policy intervention that oversaw the expansion of bank branches in India. In 2005, the Indian central bank provided incentives for commercial banks to open new branches in under-banked districts with a population-to-branch ratio above the national average. We compare households and enterprises in treatment districts with a population-to-branch ratio just above the national average to those in control districts with a ratio just below the national average. Our analysis draws on three nationally representative surveys: India Human Development Survey, Economic Census, and National Family Health Survey, providing data on a wide range of household financial variables including consumption expenditures, savings and investments, employment, wages, borrowing, and household wealth.

We find that bank branch expansion has a positive effect on household expenditures related to consumption, food, and motor vehicles, and on overall living standards in treated districts. The RD estimates also show that households in treated districts access more financial products such as bank savings accounts and life insurance policies, and invest more in longer-term interest bearing deposits. In contrast to the existing literature, we find that higher household expenditures are not accompanied by an increase in household debt. On the contrary, treated households experience a significant decline in interest payments and consumption loans. For example, there is a one-fourth decline in the monthly interest on loans paid and a one-third decline in the likelihood of taking loans for consumption, marriage or medical reasons by treated households.

In contrast to the effect on household debt, we observe a substantial increase in firm-level debt, employment, wages, and household business earnings. For example, treated firms increase borrowings from formal financial sources by 36%, number of employees by one-fifth, and employment earnings and business revenues by 14% and 25%, respectively. Disentangling the impact of financial inclusion, our results support the "business finance" view that financial inclusion impacts household well-being via the labor market effect of enhancing access to finance for firms.

A plausible reason for these results is that banks operating in emerging markets find it more profitable to lend to firms rather than households. In India for example, despite significant strides towards financial inclusion, more than a quarter of individual bank accounts remain dormant and only 10% of adults have ever borrowed from financial institutions (The World Bank, 2021).

To investigate bank incentives, we analyze lending behavior in rural versus urban districts, as the latter regions have a greater concentration of enterprises and better infrastructure to facilitate business expansion. Our results support the hypothesis that banks find it more profitable to lend to firms. First, credit growth is significantly higher in treated urban districts (50% relative to the mean) compared to rural districts (17% relative to the mean) following the policy change. Second, treated urban enterprises are significantly more likely to rely on institutional loans as their primary source of borrowing, compared to rural enterprises. Third, treated urban households have significantly higher consumption expenditures, pay lower interest on loans, have fewer consumption loans and lower debt, there is no significant impact on the financial characteristics of treated rural households.

We investigate the validity of the regression discontinuity design in several ways. First, we show that there was no difference in the number of bank branches, credits, and deposits around the population-branch ratio cut-off prior to the policy change in 2005. Following the policy change, there is a discontinuous increase in the number of banks and credit and deposits in treated districts. Second, we show that there are no pre-policy differences in household financial characteristics in treated versus control districts. Third, we find no evidence of household migration in anticipation of the policy. Fourth, local average treatment effect estimates from the RD regressions are robust to generic robustness tests, including higher order polynomials, placebo discontinuity test, bandwidth multipliers and bandwidth selectors. Fifth, we conduct a placebo test to see if the policy had any impact on growth of regional rural banks, which were not the policy priority, and find no impact. Sixth, Cramer [2020] use the same treatment condition and show that there were no other contemporaneous policy changes that had the same priority districts as that of the RBI policy. Lastly, the population-to-branch ratio around the cut-off is unlikely to be manipulated since the population data are from the 2001 population census, and bank branches data are collected by the Indian central bank.

Our findings shed light on the complex relationship between financial inclusion and household financial well-being. The results suggest that financial inclusion has important spillover effects on

the wider economy, with firms benefiting more than households. Moreover, our study underscores the need for policymakers to focus on expanding access to credit for financially constrained firms in less industrialized areas in order to promote inclusive growth.

2 Data

We use four sources of data in our analysis: (i) RBI's Master Office File (1997-2016) and Basic Statistical Returns (2005-2015) data, (ii) Panel of the India Human Development Survey 2005-2005 and 2011-2012, (iii) The National Family Health Survey (Demographic and Health Survey (DHS), 2015), and (iv) Economic Census, 2005 and 2013. In this section, we discuss the variables derived from each of the data sets.

2.1 RBI's Master Office File & Basic Statistical Returns

RBI's Master Office File (MOF) provide data on the number of bank branches in a given district. Since the policy was to incentivize commercial bank expansion, regional rural banks (RRBs) were excluded from the policy, and therefore from our analysis.[1] We use annual data on physical bank branches from 1997 to 2016 at the district level to examine the dynamic expansion of bank branches and licenses in treatment districts pre- and post-policy. We test for pre-policy smoothness around the policy cut-off using data from 1997 to 2005, and examine discontinuities after the policy with data from 2006 to 2016. Summary statistics are described in Table A1. The Basic Statistical Returns data from 2005 to 2015 provides the annual currency amount of credit and deposit of all scheduled commercial banks in urban, semi-urban and rural areas. Summary statistics of the credit and deposit in rural, semi-urban and urban areas, and in banked and underbanked districts are shown in Table A2.

2.2 India Human Development Survey Panel

The India Human Development Survey is a nationally representative panel data survey of over 40,000 households in 1,420 villages and 1,042 urban neighborhoods across India.[2] The two panels of survey are IHDS-1, conducted in 2005-2006 and IHDS-2 conducted in 2011-2012. There is an

[1] The policy level exclusion of RRBs allows us to perform placebo tests, which we show in our empirical results.

[2] IHDS is a collaborative project by the University of Maryland, the National Council of Applied Economic Research (NCAER), Indiana University, and the University of Michigan. The survey covers all states and union territories of India except for the union territories of Lakshadweep and Andaman and Nicobar Islands.

83% re-interview rate between the two surveys. We obtain the household financial well-being measures from these surveys. Since IHDS-1 was conducted a year before the branch expansion policy we use it to measure pre-policy smoothness for outcomes. IHDS-2 was conducted six years after the policy and provides the estimates for post-policy discontinuity in outcomes. IHDS-2 successfully re-interviewed approximately 83% of the 41,554 households that were interviewed in 2005 with additional replacement households, and covers 64% of the districts in 2005 (as per the 2001 census borders) and 65% of the districts in 2012 [Desai and Vanneman, 2018].

Figure A1 shows the treatment districts in IHDS corresponding to underbankedness as described by the policy cut-off, with 219 underbanked districts and 152 banked districts.[3] The survey covers wide ranging topics related to household consumption, food expenses, poverty, ownership of vehicles, earnings from work and business receipts. In addition, the survey also covers household finance variables such as bank deposits (fixed and savings), insurance products, interest on loans and sources of loans, among others. To conduct heterogeneous impact evaluations, the IHDS survey provides sufficient observations and variations for rural–urban comparisons. Attrition in the IHDS survey does not pose a threat to our identification as we only use IHDS 2 (compare households in treatment and control districts) for the analysis.

Summary statistics of the IHDS survey (overall sample and the rural-urban sample) are provided in Tables A3, A4, A5 and A6. These tables also provide the summary statistics of the variables within the range of the policy cut-off, ± 4,000. The within bandwidth summary statistics provide external validity to our design as they are similar to the full sample values, and the differences in treatment and control values for outcomes are also smaller within the bandwidth.

Our main well-being variable is the real annual per capita consumption expenditure derived from the real total household consumption expenditure using the OECD equivalent measure. Real monthly expenditure on food is computed by aggregating over the expenditures on the following items: rice, wheat, sugar, kerosene, cereals, pulses, meat, gur and sweeteners, oil, eggs, milk, milk products, cereal products, vegetables, salt and spices, tea, coffee, fruits, and processed foods. In IHDS, household poverty is based on monthly consumption per-capita and the official Planning Commission poverty line as of 2005. Poor is an indicator (0/1) variable indicating whether the household is above or below this poverty line. Ownership of motor vehicles is equal to one for

[3]For the merged IHDS panel, we have a total of 379 districts (384 in IHDS 2, 379 in IHDS 1). When we merge the panel of IHDS with RBI data, we lose an additional 8 districts because IHDS data shows Delhi divided in 8 districts, but the RBI data categorizes Delhi as one district. However, as all districts in Delhi fall into banked category, the identification is not threatened. After the final merge, we have a total merged panel of 371 districts.

households with a motor vehicle, and 0 otherwise. All other variables derived from the IHDS surveys are discussed in the results section.

2.3 Economic Census (2005 and 2013) and National Family Health Survey (2015-2016)

We use two additional national level surveys, The National Economic Census (EC, 2005 and 2013), which describes enterprise data and the National Family Health Survey (NFHS, 2015-2016), which provides additional household data. From the Economic Census, which covers all the districts in India, we observe an enterprise's likelihood of having institutional loan as a major source of finance and total employment and wage bill before and after the policy.

NFHS (2015-2016) provides a unique standard of living index for the overall sample, rural and urban areas by combining various household assets and services owned by the household.[4]

The advantage of EC and NFHS is that they are very large sample surveys (covering all districts in India). Based on EC and NFHS, we are able to provide estimates for 581 districts, separately for rural and urban areas. The banked underbanked districts covered in the NFHS survey is given in Figure A2. Summary statistics of the variables used from these data sources is available in Table A7. Living standard index is a composite measure of a household's cumulative living standard. The variable is based on a household's ownership of consumer items such as a television and car; dwelling characteristics such as flooring material; type of drinking water source; toilet facilities; and other characteristics that are related to wealth status. Each household asset for which information is collected is assigned a weight generated through principal component analysis. The resulting asset scores are used to define wealth quintiles.

2.4 Mapping and Timeline

India's district borders changed between the census in 2001 and 2011. Census 2001 had 593 districts while Census 2011 had 640 districts. For our study, we use Census 2001 and make adjustments in merging the 581 districts for which the RBI data is available and therefore, all district boundaries are traced back to Census 2001. Figure 1 shows the timeline of our study and the data.

[4]NFHS data is available for 601,509 households.

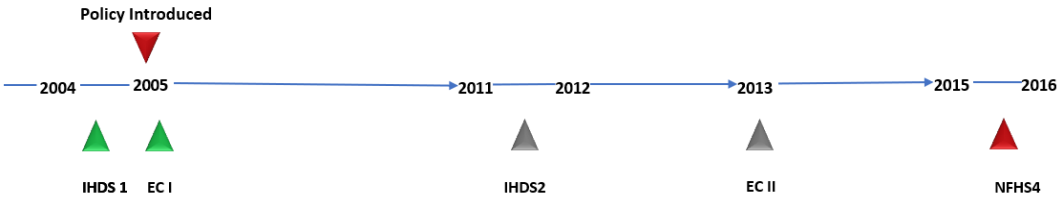

Figure 1: Timeline for the study. The three main data sets used: IHDS (2005-2012), NFHS (2015) and EC (2005 and 2013).

3 Identification

3.1 Bank Expansion Policy

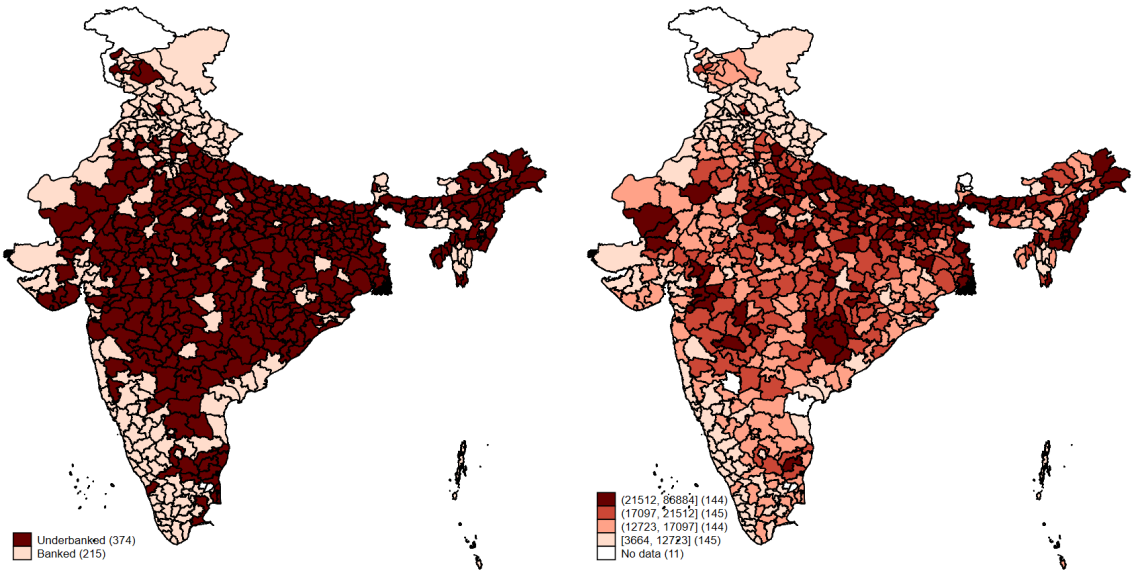
In 2005, the Reserve Bank of India (RBI) introduced a policy to incentivize commercial banks to open new consumer facing bank branches in previously underbanked locations. The criteria for being an underbanked location was based on the condition that the district had a population-to-branch ratio higher than the national average (as per the 2001 census and district boundaries). Consequently in July 2006, the RBI announced a list of underbanked districts.[5] The policy stated that banks can increase their chance of acquiring licences for opening up branches in favored locations if they open branches in underbanked districts.

We construct district-level ratios using district level population from the 2001 census and the number of scheduled commercial bank branches in the district in the first quarter of 2006 from RBI data. The national average population-branch ratio in a district is approximately 14,780 people. If a district has more than 14,780 people per bank branch it was classified as underbanked. Since 2006, the list of the underbanked districts has remained constant.

3.2 Design of RDD

Following Young [2017], Cramer [2020] and Acharya et al. [2022], we use the cross-sectional variation in the district level population-to-branch ratio in 2006 as the running variable in the regression discontinuity design.

[5] See RBI Policy Document.



Panel (A) Panel (B)

Figure 2: Banked and Under-banked Districts. 375 districts are defined as underbanked, shown in darker shades.

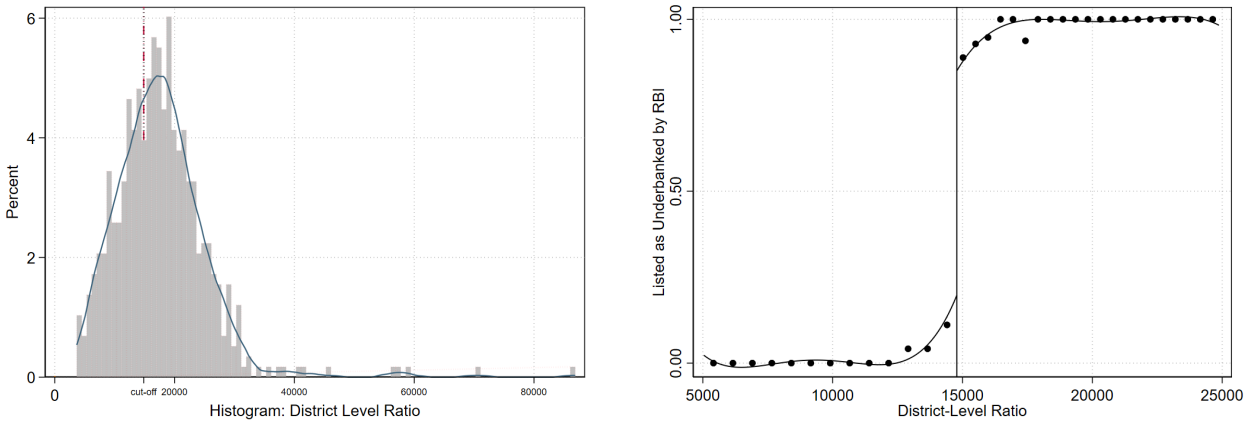
$$\frac{Population_{District(2001)}}{Number of Bank Branches_{District(2006Q1)}} > \frac{Population_{National(2001)}}{Number of Bank Branches_{District(2006Q1)}} \quad (1)$$

Equation 1 shows the condition used to identify underbanked areas. In districts where the inequality of equation 1 holds, commercial banks were incentivized to open up bank branches. Panel (A) in Figure 2 shows the districts that were considered underbanked in 2005 and Panel (B) shows the population to branch ratio at the district level with darker shades reflecting higher levels of under-banking. The maps show that unbanked districts cover a wide geographic area in the country.

Figure 3(A) shows the histogram of the bank to district population ratio. Out of 593 districts classified as either underbanked or banked by the RBI, we are able to perfectly predict the status of 581 districts. Since the RBI could have used their discretion for the classification of 12 districts as underbanked, we use a fuzzy RDD design [Lee and Lemieux, 2010] for our analysis. To check for manipulation around the cut-off, we conduct the McCrary [2008] density test. The test examines if the identification assumptions hold around the cut-off and if there are a similar number of

districts to the right and left of the cut-off. Figure A3 for the McCrary density test shows that there are similar number of districts to the left and right of the cut-off indicating no manipulation around the cut-off.

The RDD design guides the size of the optimal bandwidth for each robust bias corrected inference of the outcome variables [Calonico et al., 2020; Cattaneo and Vazquez-Bare, 2017; Imbens and Kalyanaraman, 2012]. The majority of the optimal bandwidths fall in the range of ±4,000 relative to the cut-off. Figure 3(B) shows the large jump in the probability that a district is listed



(A): Histogram (B): First Stage

Figure 3: Banked and underbanked districts. Authors' computations using RBI MOF. District borders refer to the 2001 Census. Cut off is set at 14,780.

as underbanked when the district's population to bank branch ratio crosses the national average.

We estimate the following empirical model for household financial well-being measures using non-parametric inference in a RDD framework.

$$\begin{aligned} Underbanked_d &= \gamma_0 + \gamma_1 Above_d + \gamma_2 PopRatio_d + \gamma_3 Above * PopRatio_d + \eta_d, \\ Y_{h,d} &= \beta_0 + \beta_1 Underbanked_d + \beta_2 PopRatio_d + \beta_3 Above * PopRatio_d + \epsilon_{h,d} \end{aligned} \tag{2}$$

In Equation 2, h denotes the household and d denotes the unique district in a state. In the first stage, $Underbanked_d$ is an indicator that is equal to 1 if the district is underbanked and 0 otherwise. $PopRatio_d$ is the district population to bank branch ratio. $Above_d$ is an indicator that is equal to 1 if the district population to branch ratio is higher than the national average. Since the survey sample used in our study is derived from a random stratified sampling approach, and

the treatment assignment is homogenous at the district level, following Abadie et al. [2023], we cluster standard errors at the district level.

For the outcomes of well-being $Y_{h,d}$, we do not use any covariates. Under standard continuity assumptions, the 'unadjusted' local linear estimator is consistent for the continuity-based RD treatment effect, and thus robust bias-corrected inferences can be employed [Cattaneo et al., 2021; Cattaneo and Titiunik, 2022]. $X_d \geq c$ (district ratio above national average) is the excluded instrument, and the treatment $Underbanked_d$ is the endogenous regressor. The coefficient of interest is β_1, and the estimator shows the local average treatment effects (LATE) of being in an underbanked district. We also demonstrate robustness with three other bandwidths commonly used in the literature and test for higher order polynomials.

For the first analysis of the branch expansions and increase in licenses, which are based on district population and number of existing branches in the district, we control for bank branches and licenses in 1996, which is the first year the data is available. Doing so allows us to arrive at covariate-adjusted RD estimator that remains consistent for the canonical fuzzy RD treatment effect, while offering a reduction in variance.

To estimate heterogeneous treatment effects using a sub-sample of rural and urban areas, we conduct uniform tests and tests for conditional moment equality. In addition, we check if proportion of compliers is large enough for each sub-sample, and if the sub-sample local average treatment effect estimator of the first stage is strong before conducting the heterogeneity analysis.

3.3 Testing assumptions of RD

We start by testing for pre-policy smoothness using the RBI bank branch data from 2005, IHDS-1 (2004/05) and Economic Census (2005). Table 1 shows the mean values of the outcome variables by treatment in columns 1 and 2, and the mean values of the outcomes within the optimal bandwidth in column 3 and 4. In column 5, we show the fuzzy RDD coefficients pre-policy, which show that prior to the policy, treatment districts do not have significantly higher bank branches or licenses. Also, households in treatment districts do not have higher consumption, poverty, or motor vehicle ownership in the pre policy period.

Insert Table 1 about here

The labor and credit market outcomes are also similar across treated and control districts in the pre-policy period. Treated districts in the pre-policy period do not have higher employment levels,

earnings, interest on loans, number of loans, unproductive loans or household debts. Importantly, the differences in mean values between treated and control districts decrease within the optimal bandwidth, providing empirical support for the choice of the bandwidth [Imbens and Lemieux, 2008]. The assumption of continuity of all characteristics in the sample except for being banked or underbanked would be violated if agents can manipulate the population to bank ratio in the district. Such manipulation is unlikely however since the district population is derived from the 2001 census, which was several years prior to the conception of the policy by the RBI in 2005. Also, the number of branches a bank has in the district is recorded by the RBI leaving no space for manipulation. Another potential threat to identification is household migration to underbanked districts. Table A8 shows that there is negligible and insignificant household migration into underbanked districts. Cramer [2020] shows that there is no correlation between the 2005 RBI policy and contemporaneous policies that may confound the effects of bank presence and do not find a significant impact of RBI policy at the district level. Lastly, the threat to identification in heterogeneity analysis (rural-urban) lies in the fact that a sub-sample analysis may bias the data generating process and make it non-random in RD design [Feir et al., 2016; Hsu and Shen, 2019]. To address this we use IHDS 1 and test for non-random distribution of the rural-urban sample. In Table A9, we see that the treatment effect is not conditional on the rural or urban sub-sample and does not pose a threat to the identification.

3.4 Post policy banking expansion

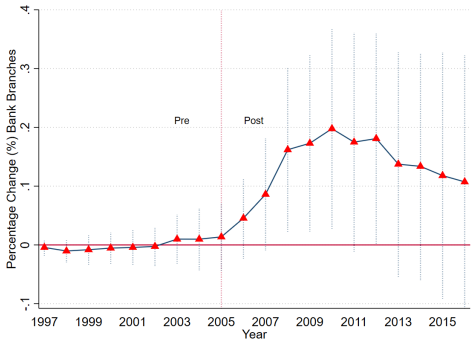


Figure 4A

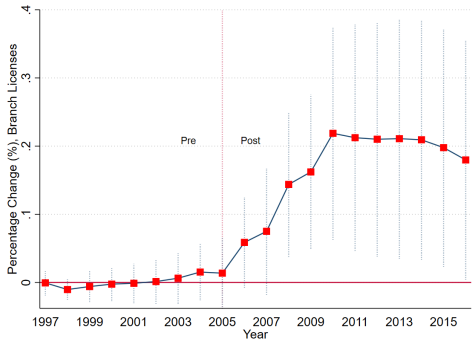

Figure 4B

Figure 4: Figure 4A and 4B depict the dynamic effects of branch licenses and branches. Results from regressions for 2005 and 2010 are described in Columns 3 and 4 of Table 2.

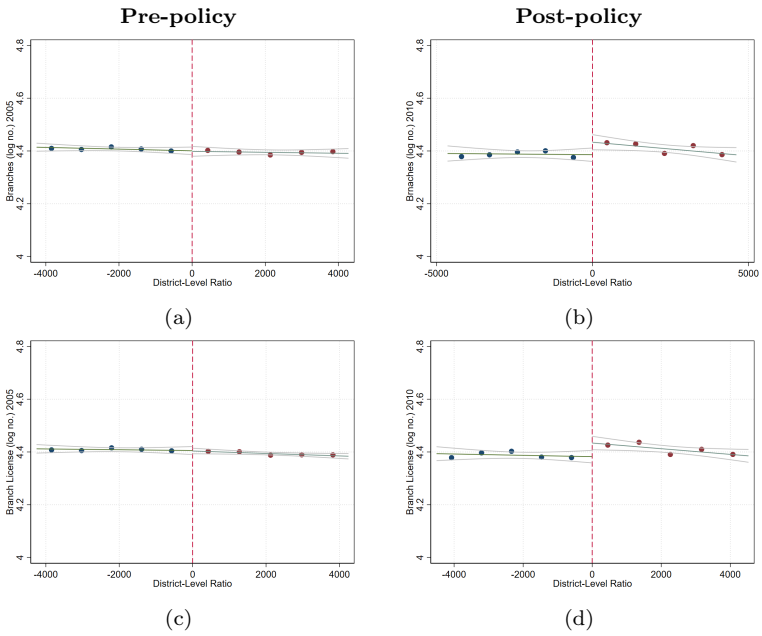

Figure 5: These graphs show binned means to the left and right of the cutoff, within the optimal bandwidth. They also show local linear polynomials to the left and right of the cutoff, with 99 percent confidence intervals. The cutoff is normalized to zero.

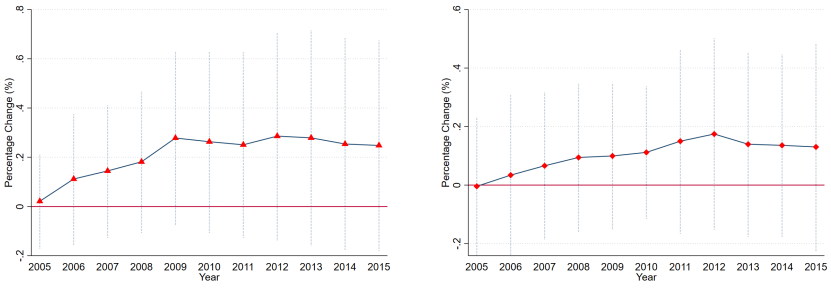
Insert Table 2 about here

We examine if the bank branch expansion policy has a significant impact on bank branches, credits, and deposits in treated districts. From the results reported in Table 2, we find that banks react positively to the incentive to open branches in underbanked districts. For example, we find an increase of 19% in bank branches and 21% in bank licenses five years after the policy in 2010. The average treatment effect on the number of new bank branches opening up in the district are conditional on the number of branches and licenses in the district in 1996. Figure 5 shows the RD graph before policy in 2005 (left) and after policy in 2010 (right) within the optimal bandwidth for bank branches and licenses. Data from 1997 to 2005 show pre-policy smoothness, and from 2005-2016 show post-policy discontinuities. While the pre-policy coefficients in 2005 are not significant, a significant discontinuity exists after 2005 in bank branches and licenses.

Figure 5A shows pre-policy smoothness before 2005 in bank branches and a discontinuous jump thereafter. Figure 5B for branch licenses also shows a similar trend. The policy had an immediate effect on increase in branch licenses once the list of underbanked districts was released in early 2006, and had a lagged effect on branch expansion, occurring mainly after 2007 (banks



A: Total Credit B: Total Deposit

Figure 6: Dynamic effects of credit and deposit expansion. The outcome variable is 'log total annual credit and deposit in Rs. at the district level for all scheduled commercial banks' winsorized and trimmed at 10% and 90% percentile.

react to license incentive after a lag). There appears a decrease in bank branch openings and licenses post 2010 at the district level. This is attributable to RBI's shift in objective from bank expansion at the district level to expansion at the village/town level [RBI, 2016; Bhaskar, 2013].

The bank branch expansion policy also affected the credit supply and deposits of commercial banks in treated underbanked districts. In Figure 6A we show the RD estimates of the percentage increase in total credit of all scheduled commercial banks from 2005-2015, with 2005 as the pre-treatment period. Figure 6B shows the corresponding percentage increase in total deposits. Although the estimates are not statistically significant at conventional levels of confidence, the graphs show an expansionary trend in total credit and deposit in the treated districts.

4 Causal impact of bank branch expansion on household financial well-being

In this section, we examine the causal impact of the bank branch expansion policy on household well-being measures including per capita consumption, household food consumption expenditure, poverty, and ownership of motor vehicles. Figure 7 shows the pre-policy smoothness in per capita consumption, food consumption, likelihood of being poor and ownership of a motor vehicle, respectively. Figure 8 shows the respective post-policy discontinuities. The post-policy graphs show a clear discontinuity in unconditional measures of household well-being. Post-policy, there is a substantial increase in per capita consumption, food expenditures and ownership of motor vehicles of households, but no reduction in poverty.

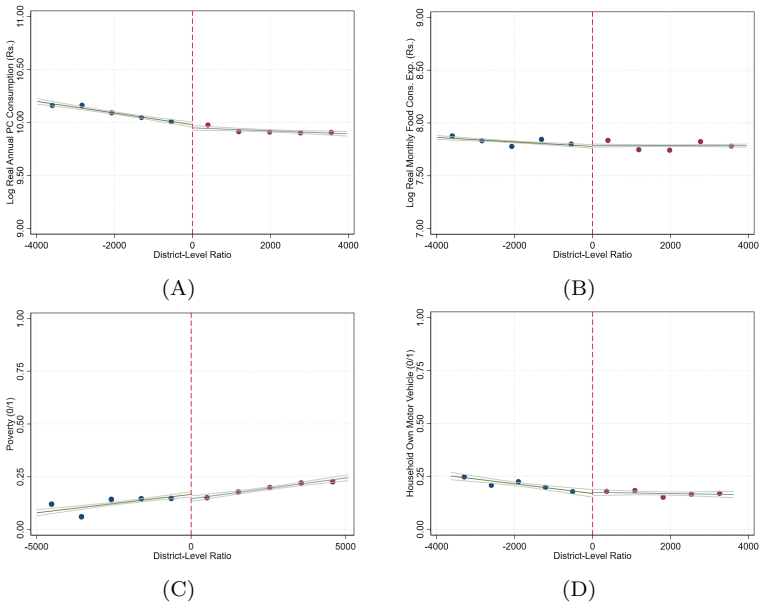


Figure 7: Smooth pre-policy covariates of household financial well-being. These graphs show binned means to the left and right of the cutoff, within the optimal bandwidth. Local linear polynomials to the left and right of the cutoff, with 95 percent confidence intervals. The cutoff is normalized to zero.

Insert Table 3 about here

Table 3 shows the results of the raw RD estimates. In column 1, we observe that households in treated districts experience a 13% increase in per capita annual consumption expenditures relative to a mean of Rs. 23,858. The corresponding monetary value is Rs. 3,095 (equivalent to $62 at the exchange rate of $1/Rs.50 in 2012). Column 2 shows that real monthly food expenditure of households in treated districts increased by 9% relative to sample mean of Rs. 2,333. In column 3, we find a negative but insignificant effect of the treatment on the likelihood of the household falling into the poor category Column 4 in Table 3 shows that households in treated districts have a 9% increase in the likelihood of owning motor vehicles.Overall, the results show that bank branch expansion significantly increases household financial well-being.

The panel household survey data allows us to capture the pre and post-policy difference in the well-being outcomes. Unique to the empirical literature, with panel data, we can compare fixed effects estimates in a RD framework. Figure 9 shows the impact of bank expansion on the financial well-being of treated versus control households. We observe that the policy significantly increases the growth rate of consumption and food expenditures, reduces the likelihood of being

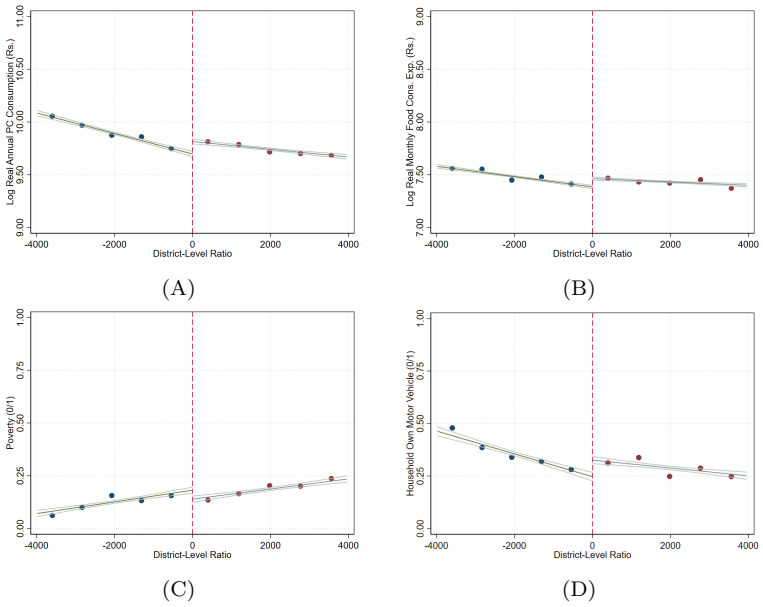

Figure 8:

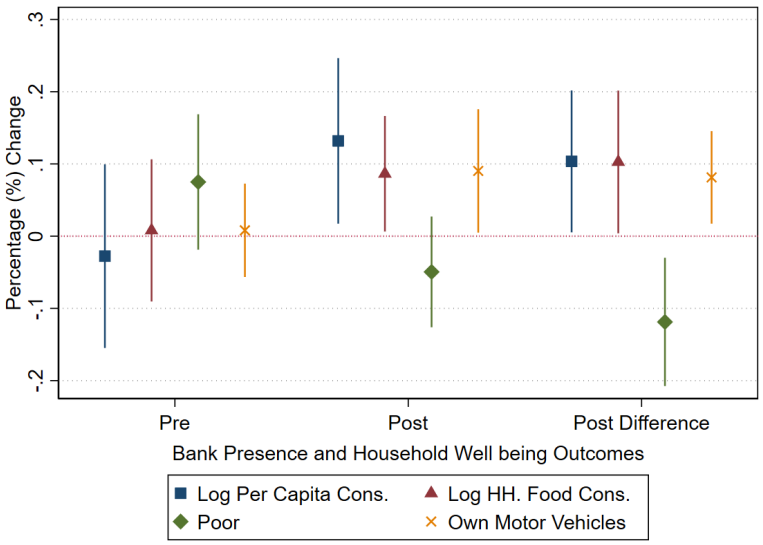

Figure 9: Pre-Policy, Post-Policy and Post-Policy Difference in Treatment Coefficients.

poor, and increases the likelihood of owning a motor vehicle. These estimates provide additional support for our post policy cross-sectional estimates.

5 Distinguishing between the household demand or business finance channels

5.1 Does bank branch expansion increase household borrowing?

According to the "household demand" channel, financial inclusion increases household consumption and financial well-being by facilitating household borrowing. In this section, we study whether the bank branch expansion policy led to more borrowing by households.

We study the impact of bank presence on the interest paid by households on loans, the total number of loans, total unproductive loans (consumption, marriage or medical expenses) taken by households, and overall household debt. Specifically, we compare these variables between treated and control districts. The results are reported in Table 4. Bank branch expansion led to a significant decrease of 0.50 percentage points in monthly interest paid on loans, a decrease of 23% from the control mean value. Households in treatment districts experienced a 33% decline in the number of loans (0.48 fewer loans). Households in treatment districts also saw a significant decline of 8.2 percentage points in the likelihood of taking up an unproductive loan, and an insignificant decrease of Rs. 2,392 ($53) in outstanding household debt.

Insert Table 4 about here

The results reported in Table 4 show that bank branch expansion does not increase borrowing by households. In fact, households pay lower interest on loans and take out fewer consumption loans, and aggregate household debt declines. These results do not support the "household demand" channel that financial inclusion increases household financial well-being through increased borrowing. Figure A5 graphically shows the pre-policy smoothness and post-policy discontinuities for the aggregate sample.

5.2 Effect of Bank Branch Expansion on Enterprise Borrowing and Labor Markets

In this section, we investigate whether bank branch expansion affects households indirectly through the labor market. Specifically, we study the impact of bank branch expansion on firm-level borrowing and employment, and household business earnings and annual income. The results are reported in Table 5.

Insert Table 5 about here

In Panel A, we study the impact of bank branch expansion on *Enterprise Institutional Loan*, which is an indicator variable that is equal to one if loans from financial institutions are a major source of borrowing for the firm. The results show that for the full sample the likelihood of borrowing from financial institutions is higher in the post-policy period compared to the pre-policy period, although the difference is not significant. We also conduct this analysis for urban and rural subsamples in Table 6 and we find that enterprises in treated urban districts are significantly more likely to rely on a loan from a financial institution as their major source of borrowing in the post-policy period.

Insert Table 6 about here

To study the labor market effects of bank branch expansion in Panel B of Table 5 we study the impact of bank presence on enterprise employment at the district level in treated districts. Post-policy, we find that employment increases in enterprises in treated districts, although the change is not significant at conventional levels. In Table 6 below we show that employment increases significantly in treated urban but not rural areas.

Next, we examine the impact on household earnings from any type of work (farm, wage, salary, animal husbandry, etc.) in Table 5, Panel C. Column 1 shows smooth pre-policy covariates for earnings and column 2 shows post-policy discontinuities. The results show that in treated districts there is an increase of Rs. 4,093 ($80) in annual employment earnings (column 2).

In Panel D of Table 5, we analyze the impact of bank presence on gross business receipts. Column 1 shows pre-policy smoothness and column 2 shows post-policy discontinuity. There is a significant increase of Rs. 65,932 ($1320) in gross business receipts in treated versus control districts.

6 Bank Lending Incentives

Our results show that bank branch expansion increases household consumption expenditures and financial well-being. However, this increase in well-being is not financed by an increase in household debt and borrowing. Instead, we find that households indirectly benefit from financial inclusion with higher employment and earnings. These results suggest that banks prefer to lend to firms rather than households. In this section we provide evidence supporting the profit motive of banks.

6.1 Rural-Urban Heterogeneity in Lending

We first examine whether the difference in credit expansion between rural and urban areas. Urban districts are likely to have more industries whereas rural districts are more agricultural. If banks prefer to lend to firms then we would expect banks to expand credit more in urban areas. The results reported in Table 6 show that banks increase credit and gain more deposits in urban areas, but there is no significant difference in credits and deposits in treated rural areas following the policy change.

Insert Table 7 about here

We find similar results for firms in treated rural versus urban areas. Banks lend to more to urban firms than rural firms. For example, in Table 7 we study the likelihood that loans from a financial institution is the main source of borrowing for the firm. Comparing the pre-policy versus post-policy coefficients in rural areas in columns (1) and (3) of Table 7, we find that the post-policy coefficient in treated rural areas is significant. However, the magnitude of this coefficient is the same pre and post-policy. In comparison, the post-policy coefficient for urban areas in Table 7, column (4) is not only significant, but 14 times higher in magnitude than the pre-policy coefficient in column (2). This result shows that following the policy change, banks lend more to firms in treated urban areas than in rural areas.

Insert Table 8 about here

Since banks lend more to firms in urban areas, we also study whether the labor market impact is greater in urban compared to rural areas. The results reported in Table 8 show that firms in treated urban areas employ significantly more workers, urban households have higher employment

earnings, and urban businesses earn higher revenues following the policy change. In contrast, there is no change in the employment, earnings, and revenues in treated rural areas after the policy change.

The results show that banks expand credit more in urban areas, and that firms in urban areas benefit more from bank branch expansion. Therefore, we study whether the impact of bank branch expansion on financial well-being varies between rural and urban households. We describe these results in Table 10.

In Table 10 we describe the results from the RD estimates for household well-being in urban and rural areas. Panel (A) of Table 10 shows that in rural areas, the policy had positive but insignificant effects on all measures of well-being. In contrast, in Panel (B) we find that in urban areas, the policy had significant positive effects on the measures of well-being. For example, the treatment had no impact on consumption expenditures of rural households, but increased household per capita consumption expenditures by 22.1 percentage points in urban areas. Household monthly food consumption also increases by 17% in urban areas. Household poverty declines significantly by 9.9 percentage points in urban areas, but there is no significant impact on rural household poverty. Motor vehicle ownership also increased by 18.8 percentage points for urban but not rural households.

6.2 Banks and Household Investments

Our results suggest that profitability concerns may lead banks to lend to firms, especially in urban areas, but not to households. In this section, we examine the impact of bank branch expansion on household investments decisions in banking products including savings accounts, life insurance policies, long-term fixed deposit accounts, pension or provident fund accounts, and securities (mutual funds, shares, stocks) or a post office account. Financial inclusion could increase household access to these financial instruments, providing households with additional funds for consumption expenditures. Moreover, the profit motive could lead banks to market financial products to households.

In Figure 10 we show the post-policy discontinuity of the household investment measures in urban versus rural areas. In Panels A-D we observe sharp post-policy discontinuities in the savings accounts, life insurance policies, long-term fixed deposit/pension accounts, and securities/post-office accounts of households in treated urban districts. We also observe a post-policy discontinuity

in the savings account of households in treated rural districts (Panel E). However, none of the other investment measures of rural households show a discontinuity.

Insert Table 9 about here

Table 9 shows the impact of bank branch expansion policy on household investments. Panel A shows results for the full sample, Panel B for rural districts, and Panel C for urban districts. From the full sample, in column 1 of Table 9 A we find that the policy led to a significant increase of 21.3 percentage points in average household bank savings in treated districts. In column 2, the likelihood of buying a life insurance product is higher although not statistically significant at conventional levels. Moreover, in column (3) there is a significant increase of 9.8 percentage points in the likelihood of opening up a fixed deposit, pension or provident fund account by households in treated districts. Lastly in column 4, we observe a positive but insignificant increase in the likelihood of investments in securities or post office account (4.4 percentage points). Overall, we find that bank branch expansion leads to a significant increase in household investments in interest bearing instruments.

In Panels B and C of Table 9 we study the effects of the policy on households in urban and rural areas, respectively. Urban households may invest more in financial products because they have more disposable income because of the positive spillover from the labor market effects of bank branch inclusion. Banks may also market financial products more heavily in urban areas where there are more rich households. The results in Panel B show that all household investment measures increase significantly in treated urban districts following the policy change. From Panel C we observe that household savings increases significant in treated rural districts, but the remaining investment variables do not change significantly.

6.3 Heterogeneity in household financial well-being

We show that profit considerations lead banks to expand credit in treated urban areas more than rural areas, and to lend more to urban enterprises compared to rural enterprises, which in turn leads urban firms to employ more workers and earn higher business revenues, increasing urban household earnings from employment. Below we examine if the heterogeneity in bank lending behavior also generates heterogeneity in household financial well-being across urban versus rural areas.[6]

[6]Table A10 and A11 shows the pre-policy insignificance of the treatment effect on RD estimates for rural and urban areas. Figure A4 shows the pre-policy smoothness in rural areas and Figure A4 shows the corresponding pre-

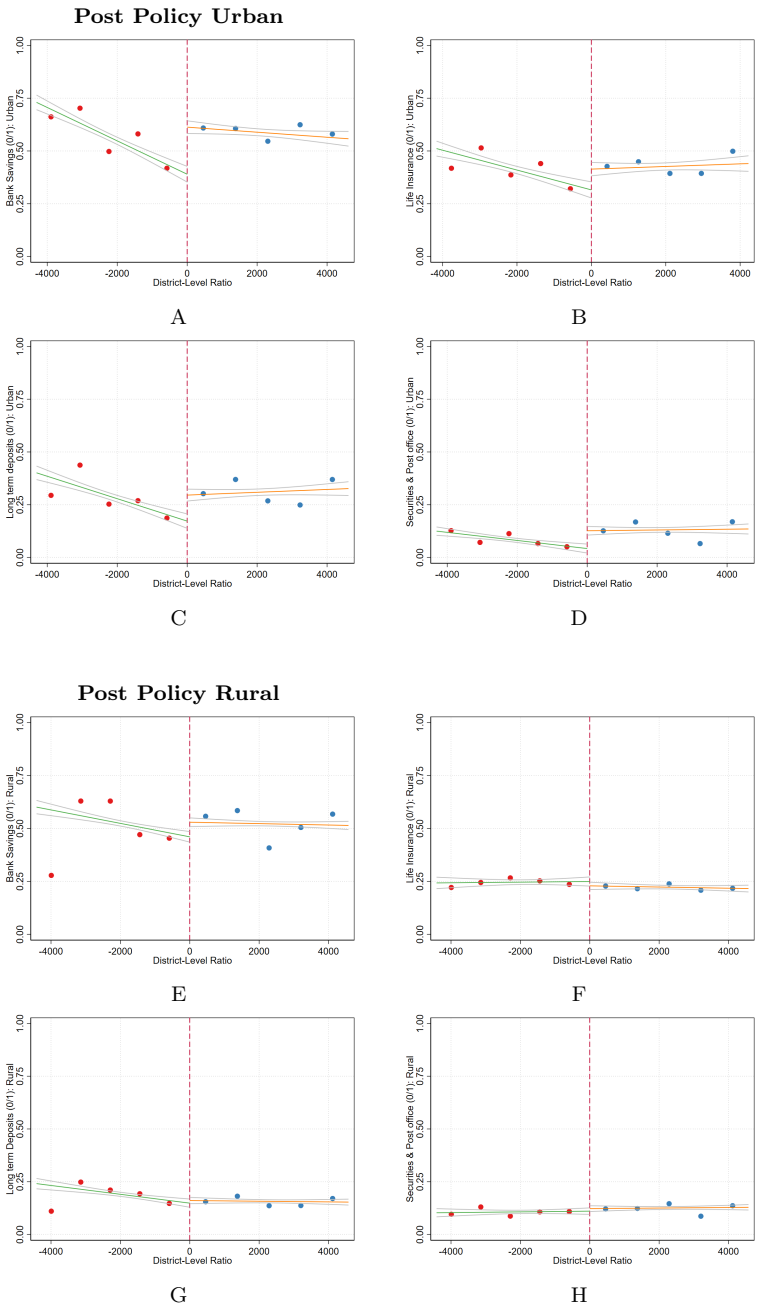

Figure 10: Post- policy discontinuity in bank presence and household investments in rural and urban areas.

Insert Table 10 about here

In Table 10 we study the impact of bank branch expansion on household financial well-being in urban and rural districts. From the results reported in Panel A of Table 10 we observe that households in treated urban districts experience significant improvement in well-being across all the measures.

Figure 11 shows the post-policy estimates of the treatment in rural and urban areas. Figure 11 (a), (b), (c), and (d) show no clear discontinuities in outcomes in rural areas with the treatment, while figure 11 (e), (f), (g), and (h) show clear discontinuities in urban areas. Almost all of the positive effects on well-being outcomes are driven by urban areas.

6.4 Low income and socially disadvantaged households

We analyze the impact of the branch expansion policy based on household income groups, social group, and education levels. Specifically we construct income quintiles; categorize households belonging to Scheduled Caste, Scheduled Tribe and Muslim households as marginalized; and lastly, denote Literate households as those with a literate adult as 1, and 0 otherwise.

Figure 12 shows that for all income quintiles, the impact of the policy is larger in urban areas compared to rural areas. Interestingly, poorer households benefited more in urban areas owing to the larger labor market effects compared to poorer households in rural areas. We also find that households belonging to marginalized social groups, and literate households benefited more in urban areas as compared to their rural counterparts (see Figure 12).

7 Robustness and Placebo Tests

7.1 Living Standards Index

We check the robustness of the household well-being measures by using an alternative measure of well-being - the household living standard index in the NFHS 2015 data. The results are reported in the Appendix Table A12. They show that the policy had a long-term effect on living standards in treatment districts. For example, the policy led to a 9.4% increase in living standards for the aggregate sample, compared to the control mean of 1.282 (column 1). An important placebo

policy smoothness in urban areas for all the household well-being measures. Pre-policy smoothness of heterogeneous treatment effects lends credibility to our post-policy analysis.

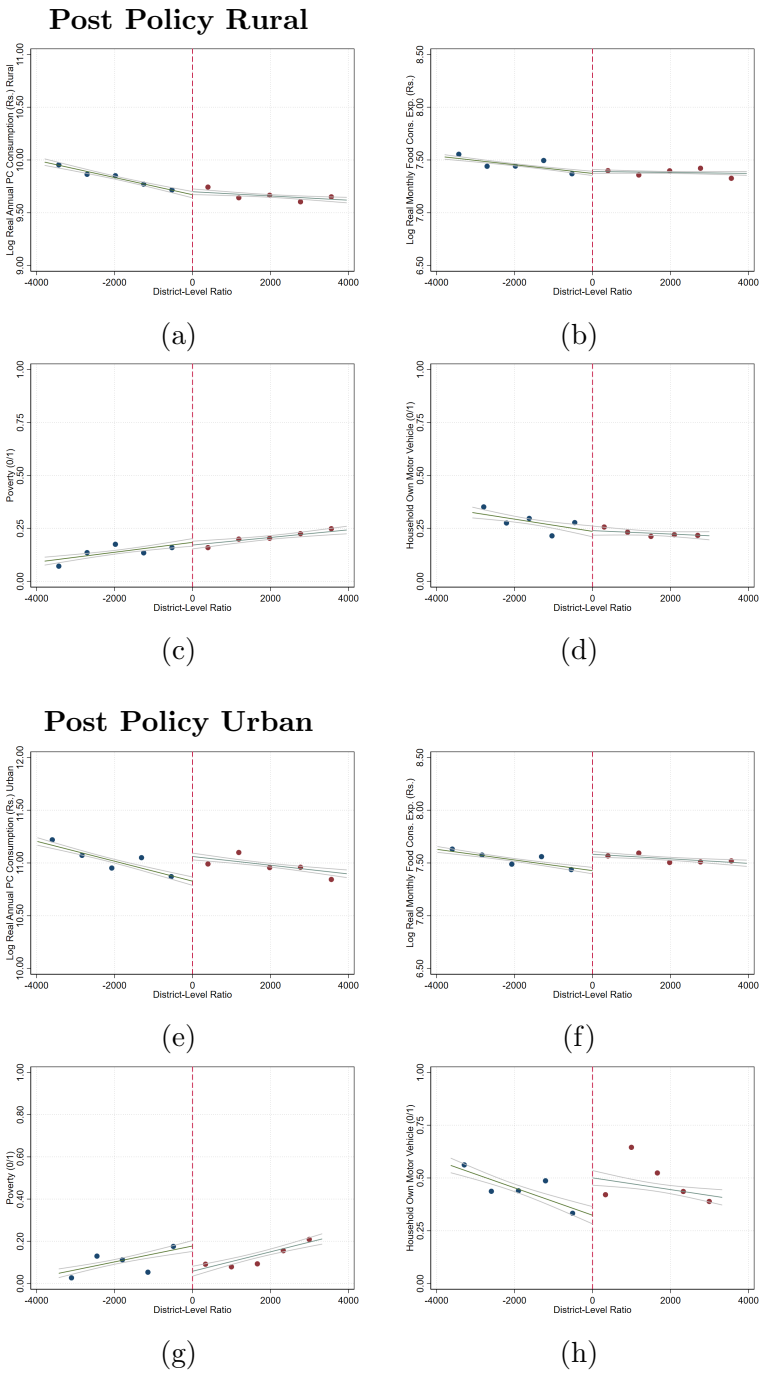

Figure 11: Post policy discontinuity in household well-being in rural and urban areas. Fig (a), (b), (c) and (d) correspond to rural areas, and figures (e), (f), (g) and (h) correspond to urban areas. Source: Authors' computations using RBI Master Office File and IHDS Data (2012).

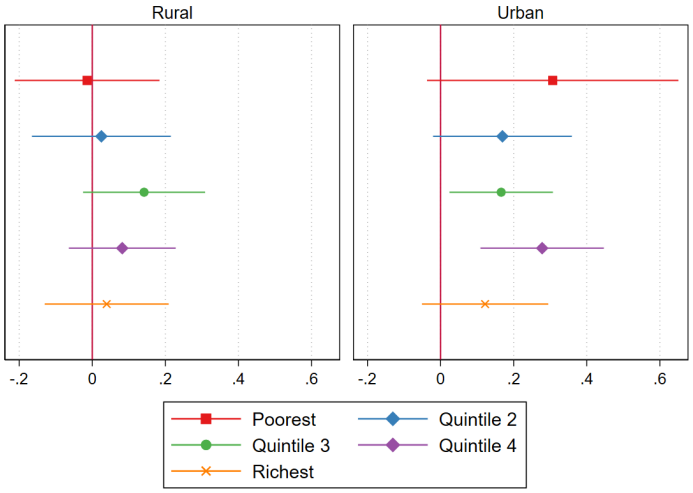
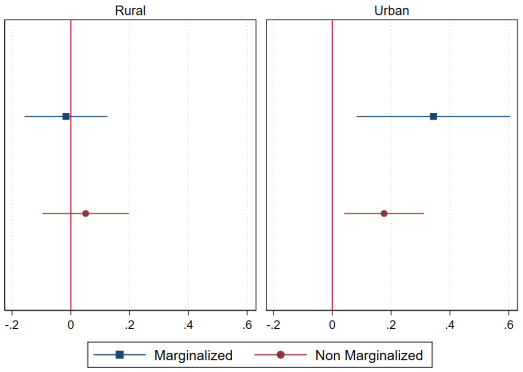
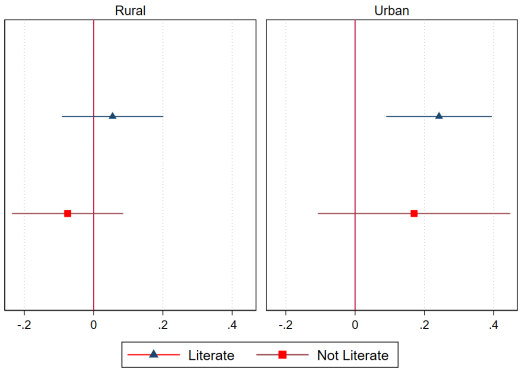
test for robustness that emerges from the policy design of incentivizing commercial banks is that there should not be any significant positive effect on the number of regional rural banks in the



A: Treatment Effect by Income Quintiles



B: Treatment Effect by Caste Marginalization



C: Treatment Effects by Adult Literacy

Figure 12: Panel A shows local Average Treatment Effects of bank branch expansion on log real annual per capita consumption expenditure in rural and urban areas by income quintiles. X-axis measures percentage (%) change. Panel B Depicts the dynamic effects of bank branch expansion on log real annual per capita consumption expenditure in rural and urban areas by caste based marginalization and Panel C by adult literacy. Source: Authors' computations using RBI Master Office File and IHDS 2012.

treatment districts which were excluded from the policy agenda. Table A18 shows that there was an insignificant effect of the policy on the number of regional rural banks in the treatment districts.

7.2 Robustness of RD specification

We estimate quadratic approximations of the RD coefficients, which is the highest polynomial approximation that researchers should apply (Gelman and Imbens [2019]). The results are similar to those obtained in the main analysis (linear estimations) and are reported in the Appendix Tables A13, A14, A15, A16 and A17. We also aggregate the financial well-being outcomes at the community (village/primary sampling unity) and check for robustness at community level. Results in Table A19 shows that bank presence has a significant positive impact on community's financial well-being.

We also conduct the classical regression discontinuity robustness test by examining smoothness around placebo cut-offs. We analyze two placebo cut-offs on each side of the true cut-off (normalized to zero), i.e, -3000, -1000, 1000 and 3000. The choice of placebo is based on having enough observations on each side of the cut-off. Results are reported in the Appendix, Table A20 and A21. We find no evidence of significance in p-values of the RD estimates in any of the placebo cut-offs considered.

We test whether the coefficients remain statistically significant when using different levels of the bandwidth. In this approach, we examine bandwidth multipliers in the range of 0.5 to 1.5. For instance, if the MSE-optimal bandwidth is 4,000, we examine bandwidth in the range from 2,000 to 6,000 (i.e, 2,000, 3,000, 4,000, 5,000 and 6,000). The results are reported in the Appendix Table A22 and A23. For 0.50x bandwidth multiplier, we find that motor vehicle ownership, earnings from employment, and long-term deposits, which are significant at RD robust bandwidth, are no longer significant for the aggregate sample. For 0.75x bandwidth multiplier, all results which were significant with the RD robust bandwidth are also significant. For 1.25x bandwidth multiplier, we lose significance for the living standard index, and for 1.5x bandwidth multiplier, we lose significance for living standard index, interest on loan and long-term deposits. We anticipate the estimates with bandwidth multipliers to be stronger for urban areas compared to the aggregate results.

Lastly, we also test the robustness of the bandwidth selectors. For the main results we use the default MSE-optimal bandwidth selector by Calonico et al. [2019, 2014] that chooses identical bandwidths to the left and right of the cut-off. We also use the two sided MSE-optimal selector which separately chooses bandwidths to the left and right of the cut-off. Additionally, we use two other bandwidth selectors, first the selector suggested by Calonico et al. [2020] that optimizes

the coverage error rate (CER), which also chooses identical bandwidths to the left and right of the cut-off, and the two-sided CER-optimal bandwidth selector, which separately chooses robust bandwidths to the left and right of the cut-off. The results are reported in Tables A24 and A25 with different bandwidth selectors.

MSE-optimal bandwidth selector shows our main results at the aggregate level. With the two sided MSE-optimal results, we lose significance in living standard index and long term deposits while we gain significance for aggregate employment at the district level. With the CER optimal method, we lose significance for ownership of motor vehicles, and when using two-sided CER optimal method, we gain significance in result for poverty reduction, but lose significance for living standard index, interest on loan and bank savings.

Overall, the robustness test for quadratic estimations, placebo cut-off, bandwidth multiplier and bandwidth selector methods show that our aggregate results are robust to standard RD robustness tests.

8 Conclusion

We use a nation-wide natural experiment in India to disentangle the impact of financial inclusion on household well-being. Using a regression discontinuity design based on this policy, we show that bank branch expansion has a significant positive impact on household consumption, financial investments, and other measures of financial well-being. Contrary to the "household demand" view of what drives household well-being, we find that household debt and borrowing do not increase. Instead, bank branch expansion leads enterprises to borrow more, hire more workers, and pay higher wages. Consistent with the profit motive of banks, we show that banks prefer to lend to firms not households, and in urban areas where there are more firms and better infrastructure. Our results suggest that financial inclusion has important spillover effects where households benefit indirectly from the labor market effects of credit expansion.

Notes: $*p < 0.1$, $**p < 0.05$,$***p < 0.01$. Standard errors in parentheses clustered at the district level. Long term deposits is dummy variable which takes the value 1 if the household has a fixed deposit account in a bank or has pension fund or other saving schemes, and 0 otherwise. Life insurance is a dummy variable which takes the value 1 if the household head has a life insurance product either from the government or private sources, 0 otherwise. Securities and Post Office Account is a dummy variable with value 1 if the household has bought any Mutual Fund/Unit Trust/Share Market/Bonds or Post Office Account (Recurring deposits, farmer development certificate, etc.), 0 otherwise. Bank savings is a dummy with value 1 if the household has a savings/current account in the bank.

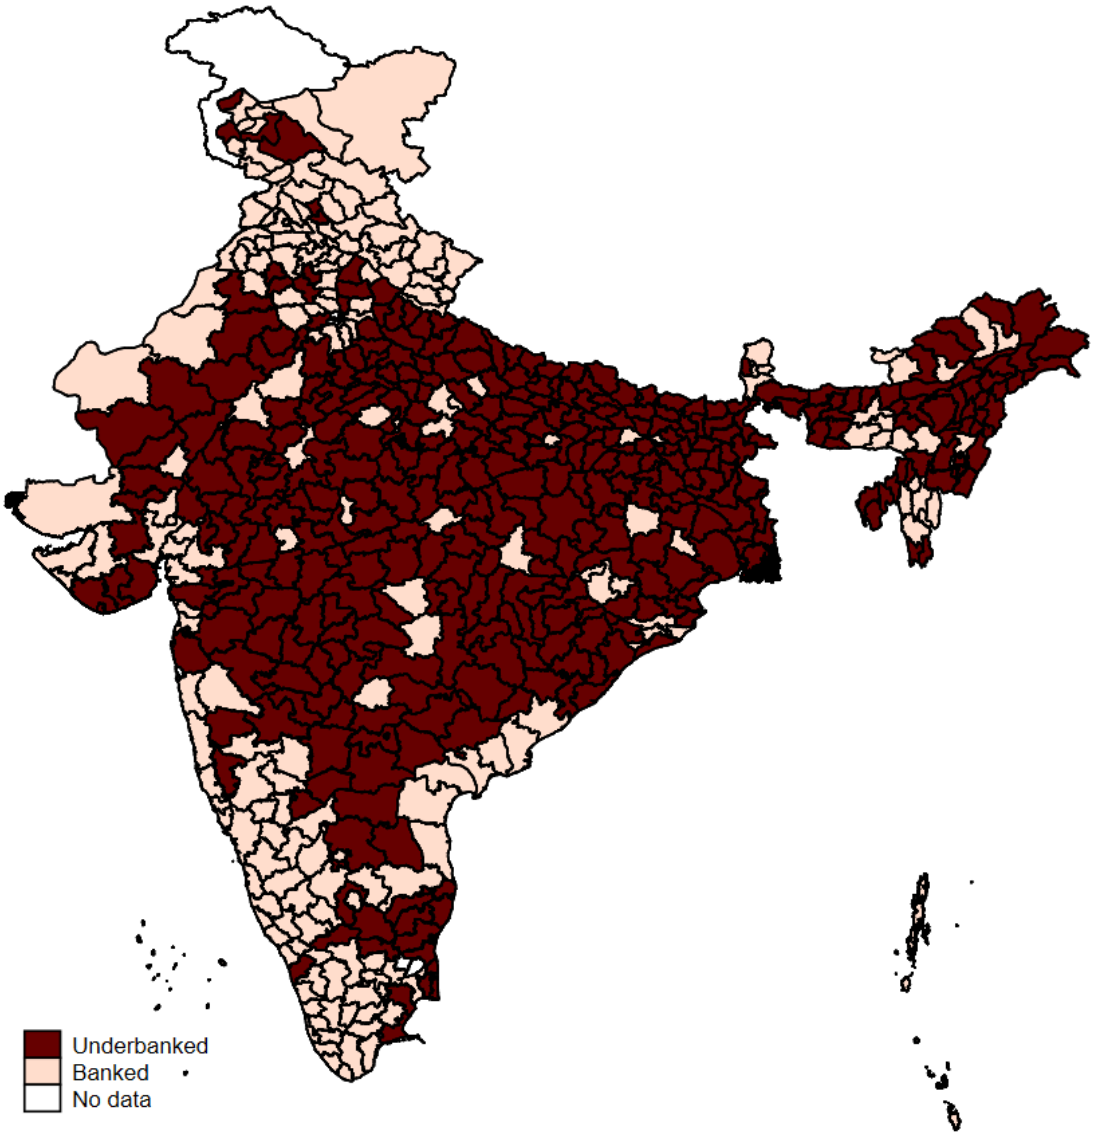

Figure A2: In NFHS, interviews were conducted in all districts. Source: authors' computations using NFHS (2015-2016) and MOF RBI Merged Data.

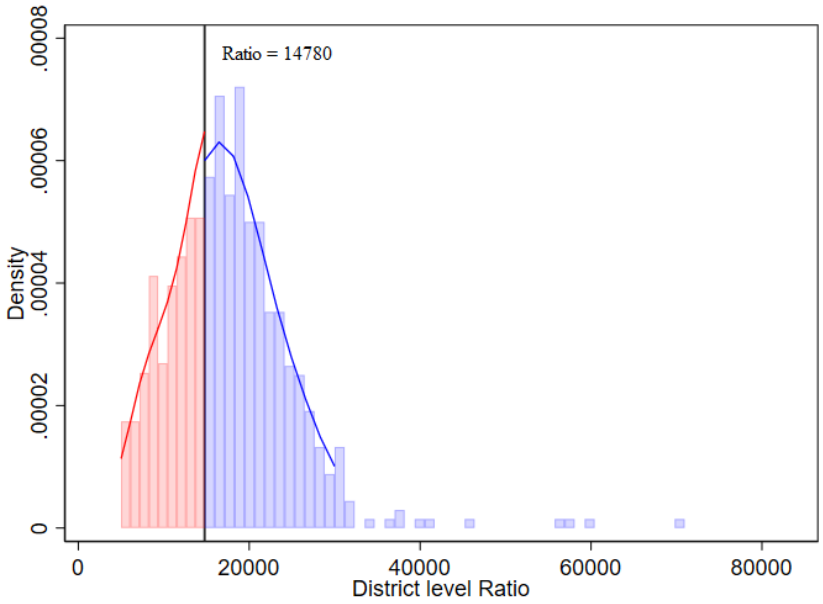

McCrary RD density test

Figure A3: Banked and Underbanked Districts. District borders refer to the 2001 Census.

Notes: The McCrary Discontinuity estimate is -0.1996 with a p-value of 0.8418. For details about the test, please see McCrary (2008). Source: Authors' computations using RBI Master Office File.

Table A1: Branch Summary Statistics

	All districts				**[-4000,+4000]**			
	1996	2004	2010	2016	1997	2004	2010	2016
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Branches (no.)	67	74	107	177	72	79	117	199
	(82)	(98)	(151)	(231)	(64)	(72)	(110)	(184)
Branch License (no.)	67	75	107	120	72	80	117	133
	(82)	(100)	(156)	(184)	(63)	73)	(113)	(133)
Observations	581	581	581	581	223	223	223	223

Notes: Standard deviations in parentheses. Raw data from RBI at the District level. Regional rural banks are excluded from the analysis. Between 2004 (pre policy) and 2016 (post policy), the final year of the last survey, we observe a large increases in branch openings of 130 percent, and similarly, a large increase in the number of branch licenses of 90 percent, in the average district. Districts with a population-to-branch ratio in the range of ± 40,00 of the policy cutoff generally have a higher number of branches and licenses on average.

Notes: Data derived from the annual amount of credit and deposit (annual balance sheet report, BSR) in Rs. of all scheduled commercial banks. Source: RBI, BSR data, 2005-2015. Log credit and deposit variables are derived by winsorizing and trimming the respective level variables (Rs.) at 10th and 90th percentile and then taking natural log of the level variables.

Table A3: Households Summary Statistics (IHDS)

	IHDS 1 (2004/2005)		IHDS 2 (2011/2012)	
	All districts	[-4000, +4000]	All districts	[-4000, +4000]
	(1)	(2)	(3)	(4)
Real Ann. PC Cons (Rs.)	25,059	25,080	21.130	21,143
	(14,572)	(14,259)	(13,108)	(13,024)

Author's elaboration from Economic Census 2005 and 2013 and NFHS (2015-2016). Variables from Economic census are winsorized and trimmed at 5^{th} and 95^{th} percentile. Variables from NFHS are winsorized and trimmed at 1^{st} and 99^{th} percentile.

Table A8: Negligible Migration

	Migration 5 Years (Yes/No)		Seasonal Migration (Yes/No)	
	(1)	(2)	(3)	(4)
Treatment	0.005	0.004	0.012	0.009
	(0.009)	(0.008)	(0.014)	(0.013)
Control Mean	0.018	0.018	0.037	0.040
First Stage	0.78	0.79	0.78	0.79
Bandwidth	4,549	4,985	4,203	4,661
Efficient Observations	21,746	22,804	20,594	22,270
Observations	39,084	39,084	39,265	39,265
Baseline Controls	Yes	No	Yes	No

$*p < 0.1$, $**p < 0.05$,$***p < 0.01$. Standard errors in parentheses clustered at the district level. Notes: in table A8 above, the first row 'Treatment' provides the main coefficient of interest, β_1.

Table A9: Bank Expansion Validity with Survey Sub-sample Check

	(1)	(2)	(3)
	Full Sample	Rural Sample	Urban Sample
Treatment	-0.005	-0.002	0.003
	(0.150)	(0.183)	(0.165)
RD robust p values	0.939	0.896	0.833
Two stage q values	0.991	0.994	0.892
First Stage	0.77	0.76	0.78
Bandwidth	4,339	4,126	4,798
Efficient Obs.	276	257	296
Baseline Controls	No	No	No
Observations	581	581	581

Notes: $*p < 0.1$, $**p < 0.05$, $***p < 0.01$. Standard errors in parentheses clustered at the district level. Notes: in table A9 above, 'Treatment' provides the main coefficient of interest, β_1 which shows if the aggregate, rural or urban sample when analyzed separately satisfy the randomization required to estimate the causal effects. Since the β_1 coefficient is insignificant for the aggregate and the rural and sub-samples, we can say that the aggregate sample and the sub-samples from the IHDS are not affected by the treatment assignment of districts as underbanked, which implies a clean randomization, and allows us to estimate the local average treatment effects.

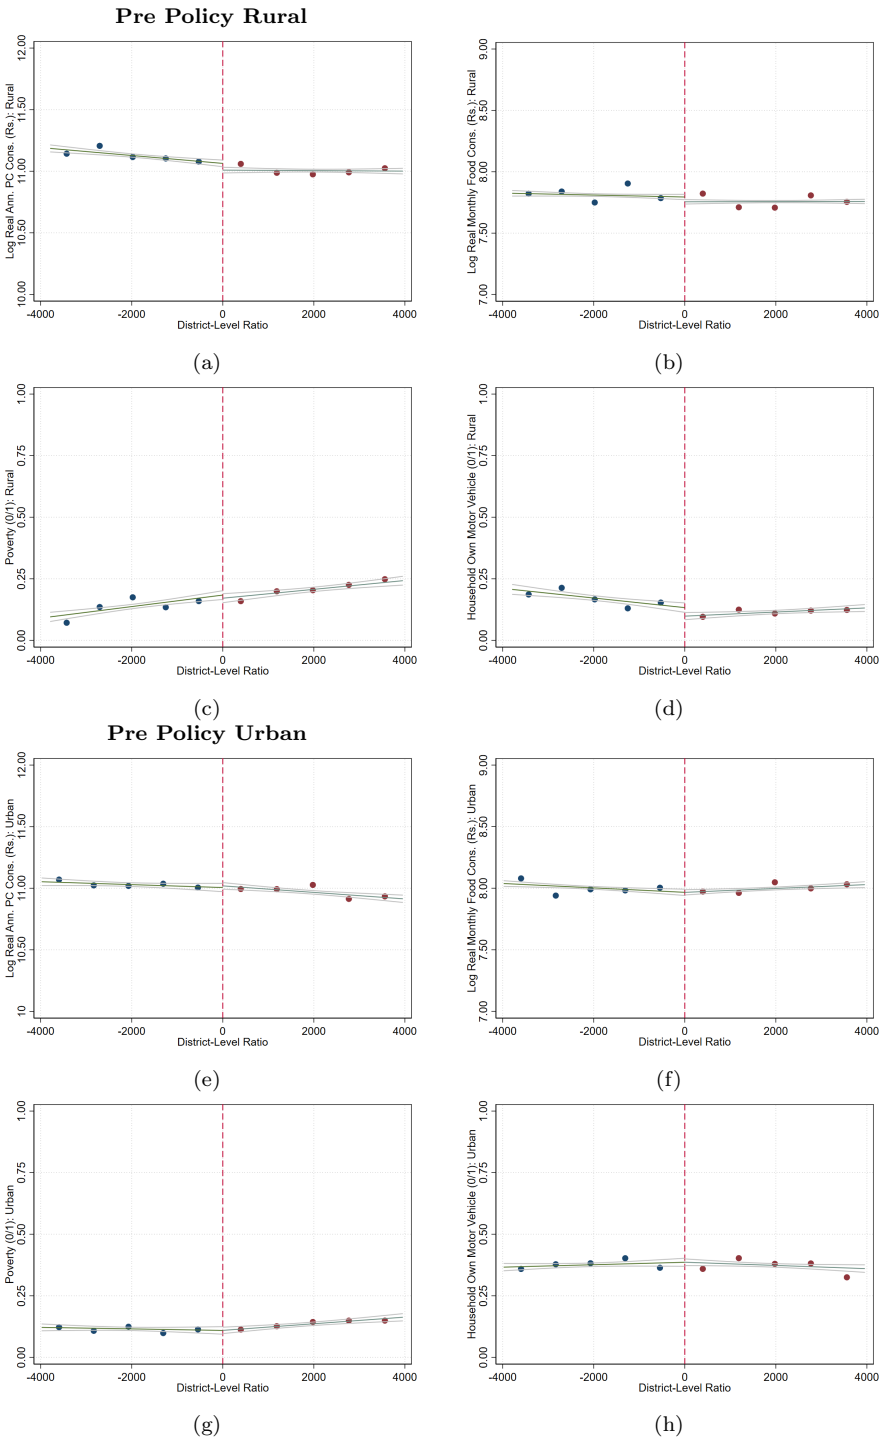

Figure A4: Pre policy smoothness in rural and urban areas. Fig (a), (b), (c) and (d) correspond to rural areas, and figures (e), (f), (g) and (h) correspond to urban areas.

Notes: Source: Authors' computations using RBI Master Office File and IHDS Data (2005).

Table A10: Bank Presence and Household Well-being in Rural and Urban Areas, Pre-Policy
